1 Introduction:

We have two ways for analyzing any algorithm, mathematically or empirically. Both algorithms nonrecursive and recursive, can be analyzed mathematically. Though these techniques can be applied successfully to many simple algorithms, not all.

In fact, even some seemingly simple algorithms have proved to be very difficult to analyze with mathematical precision and certainty (average case for quicksort). To avoid this complexity we use empirical analysis.

Empirical analysis gives us an idea of how well a given algorithm will perform in a specific situation, it is also important in comparing two algorithms which may or may not have the same order of complexity – when would we use one and not the other.

In this report we use empirical analysis to analyze two algorithms first one is a brute-force algorithm to check whether all the elements in a given array of n elements are distinct, the second algorithm uses quicksort to sort the list before checking the uniqueness of elements in a list with other operations.

2 Empirical Analysis of Algorithms:

2.1 The Experiment Purpose:

The purpose of this experiment is to compare the efficiency of 2 approaches to check the uniqueness of elements in a list, the first one uses brute-force algorithm with an unordered list, the second one uses a preordered list using quicksort. then Decide which algorithm is faster and compare results with the theoretical assertion about the algorithm's efficiency.

2.2 The Efficiency Metric:

We have two ways to measure the efficiency of an algorithm:

- 1- insert counter into a program implementing the algorithm to count the number of times the algorithm's basic operation is executed.
- 2- time the program implementing the algorithm using some functions such as `console.time` then `console.timeEnd` in javascript.

The first way is straightforward and machine independent. we should only be mindful of the possibility that the basic operation is executed in several places in the program and that all its execution needs to be accounted for. Also, we should test the program each time when we modify it and ensure that we solve the problem and have the correct count for the basic operation.

For algorithms that depend just on the size n we always have the same result when we run the program but for algorithms that depend on both the size and the instance, we can run the program several times then take the average for the results. In this case, we don't care about the machine performance we focus on the algorithm itself so it's clear that we can use the counter to analyze the two algorithms and compare them. for our purpose, it's not useful to use runtime as a metric because we don't focus on the performance of a specific machine on this algorithm.

For the reasons above I decided to use counter to count the number of times the algorithm's basic operation is executed.

2.3 input sampling strategy:

For input sampling, we will start with a small size 2000 and increase it by a constant value (each time add 1000 to the previous size) until we have ten sizes end with size 11000 (the sizes will be 2000, 3000, 4000, 5000, 6000, 7000, 8000, 9000, 10000, 11000). The reason behind choosing these sizes in this pattern is that ten points are enough to give a clear graphical representation and does not slow down the browser used to test the efficiency of the algorithm. In this experiment, we have two algorithms and each one has different cases worst, average and best. The range for the input will be 0x9, 0xff, 0xffffeee, 0xffffeeee depend on the algorithm to be studied and the cases for each one.

Brute-force algorithm depends on both size and instance(all element will be unique or will have some elements have the same value). For the worst case use the range 0xffffeee in a method called fill that uses Math.random() To fill the list with a unique value for the sizes we previously identified. For the average case use the range 0xffffeee to generate a list that may contain two elements that have the same value. Because the best case is not important when we study the efficiency of any algorithm, we will ignore it.

Presorted algorithm uses the quick sort algorithm which depends on the size and value of the partition element (we use random index for the partition so we can't achieve the worst case so we can use a small range to have a list with the same element so each time the partition element will divide the list into a list with no element and another list with the same element minus the partition element). For the worst case use small range such as 0x9 to have same elements with the same value in the list for the average case I use range 0xee that generate

Several instances of the same size are included in the sample, the averages or medians of the observed values for each size should be computed and investigated instead of or in addition to individual sample points.

2.4 Prepare and implementation algorithms:

We have two different algorithms to solve the same problem and use another algorithm to sort the list in the Presorted algorithm and another function to fill the list randomly with a specific range:

- **brute-force unique elements algorithm:**
(from textbook ch2 section 2.3 page 89)
- **Presort Element uniqueness algorithm:**
(from textbook ch6 section 6.1 page 203)
- **Quick sort algorithm used by Presort Element uniqueness algorithm:**
(From Dr. Muhammed Al-hashimi website sortcomp.js) with the other method used by this algorithm such as fill method

Tools used in this experiment:

- JavaScript language: using to implement the code .

- Firefox browser: using to run the code and show the output on the console .
- Microsoft Excel: using to represent result data (see 2.6) .

2.5 Generate a sample of input

Using the fill method to generate random numbers with a specific range for each case as we describe in 2.3 . Each run for the program will generate the input depend on which case we want to test, so we have to change the range and call the right function for each case. See the comments in the code

2.6. Data Observed from Running the Algorithm:

| size | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | average |

Table8: result for the presorted algorithm average case (time)

2.7 Analyze the data obtained:

From the previously observed data, the following can be inferred:

We can compute the ratios $M(2n)/M(n)$ and see how the counter reacts to doubling of its input size. As we discussed in Section 2.2 from the textbook, the ratios determine the behavior of algorithms in one of the basic efficiency classes. such ratios should change only slightly for logarithmic algorithms and most likely converge to 2, 4, and 8 for linear, quadratic, and cubic algorithms, respectively—to name the most obvious and convenient cases.

- Table1: the data represent the worst case for the brute force algorithm. by computing the ratios $C(2n)/C(n)$ when we double its input size we have:

$$\frac{C(8000)}{C(4000)} = 4.000500125, \quad \frac{C(4000)}{C(2000)} = 4.0010005,$$

$$\frac{C(6000)}{C(3000)} = 4.000666889$$

The function increases fourfold then it should be quadratic

$$C_{\text{worst}}(n) = n^2 \in \Theta(n^2).$$

- **Table2:** the data represent the average case for the brute force algorithm. by compute the ratios $M(2n)/M(n)$ when we double its input size we have:

$$\frac{C(8000)}{C(4000)} = 4.000500125, \quad \frac{C(4000)}{C(2000)} = 4.0010005,$$

$$\frac{C(6000)}{C(3000)} = 4.103258008,$$

The function increases fourfold then it should be quadratic

$$C_{\text{avg}}(n) = n^2 \in \Theta(n^2).$$

- **Table3:** the data represent the worst case for the presorted algorithm. by compute the ratios $M(2n)/M(n)$ when we double its input size we have:

$$\frac{C(8000)}{C(4000)} = 3.962682823, \quad \frac{C(4000)}{C(2000)} = 3.927221796,$$

$$\frac{C(6000)}{C(3000)} = 4.000666889,$$

The function increases fourfold then it should be quadratic

$$C_{\text{worst}}(n) = n^2 \in \Theta(n^2).$$

- **Table4:** the data represent the average case for the presorted algorithm. by compute the ratios $M(2n)/M(n)$ when we double its input size we have:

$$\frac{C(8000)}{C(4000)} = 2.9923631, \quad \frac{C(4000)}{C(2000)} = 2.397656,$$

$$\frac{C(6000)}{C(3000)} = 2.0732053, \quad \frac{C(10000)}{C(5000)} = 2.3649608,$$

The function increases slightly more than twofold then it should be linearithmic $n \log_2 n$

$$C_{\text{avg}}(n) = n \log_2 n \in \Theta(n \log_2 n).$$

We can use the same steps for the time metric which leads to the same result.

2.8 Comparison between algorithms:

As a conclusion from the last step we have the following:

Brute force algorithm:

- $C_{\text{worst}}(n) = n^2$.
- $C_{\text{avg}}(n) = n^2$.

Presorted algorithm:

- $C_{\text{worst}}(n) = n^2$.
- $C_{\text{avg}}(n) = n \log_2 n$.

There is A convenient method for comparing the orders of growth of two specific functions is based on computing the limit of the ratio of two functions $t(n)$ is the presorted algorithm, $g(n)$ is the brute-force algorithm.

Three principal cases may arise:

$$\lim_{n \rightarrow \infty} \frac{t(n)}{g(n)} = \begin{cases} 0 & \text{implies that } t(n) \text{ has a smaller order of growth than } g(n) \\ c & \text{implies that } t(n) \text{ has the same order of growth as } g(n) \\ \infty & \text{implies that } t(n) \text{ has a larger order of growth than } g(n) \end{cases}$$

Using excel find the limit for the sizes (2000, 3000, 4000, 5000, 6000, 7000, 8000, 9000, 10000, 11000)

| size | worst |
|-------|-------|
| 2000 | 1 |
| 3000 | 1 |
| 4000 | 1 |
| 5000 | 1 |
| 6000 | 1 |
| 7000 | 1 |
| 8000 | 1 |
| 9000 | 1 |
| 10000 | 1 |
| 11000 | 1 |

1 is constant implies that both presorted algorithms and brute-force algorithms have the same order of growth for the worst case.

| size | average |
|-------|----------|
| 2000 | 0.005483 |
| 3000 | 0.00385 |
| 4000 | 0.002991 |
| 5000 | 0.002458 |
| 6000 | 0.002092 |
| 7000 | 0.001825 |
| 8000 | 0.001621 |
| 9000 | 0.00146 |
| 10000 | 0.001329 |
| 11000 | 0.00122 |

The result 0 implies that the presorted algorithm has a smaller order of growth than the brute-force algorithm for the average case.

3 conclusion:

Empirical analysis used when it is difficult to analyze with mathematical precision. we apply the steps of the empirical analysis and found the time efficiency for two algorithms using the counter as metric and collect physical time (will have the same result). Using a counter for comparing the efficiency is more accurate and have stable result independent on the machine we use.

The result matches the mathematical result discussed in the textbook as follow:

Brute force algorithm:

- $C_{\text{worst}}(n) = n^2$.
- $C_{\text{avg}}(n) = n^2$.

Presorted algorithm:

- $C_{\text{worst}}(n) = n^2$.
- $C_{\text{avg}}(n) = n \log_2 n$.

The comparison between the two algorithms :

Presorted algorithm is much better in the average case ($n \log_2 n$) than brute-force one (n^2), but in the worst case they both have the same order of growth (n^2) because the worst case in Presorted algorithm is rear to happen that makes the Presorted algorithm a good choice.
